WHAT IS YOUR DIAGNOSIS?

Multiple whitish papules on the posterior neck of an elderly woman^{☆,☆☆}

Abstract White fibrous papulosis of the neck is a rare entity, with fewer than 50 cases described. It is a benign pathology whose main interest lies in its broad differential diagnosis, especially with pseudoxanthoma elasticum. The authors report the case of a 77-year-old woman with multiple yellow-white monomorphic papules on the posterior cervical region, with years of evolution. Cutaneous biopsy revealed a nodular area in the superficial and middle reticular dermis, with slight thickening of the collagen fibers and focally enlarged elastic fibers, aspects highlighted in the Verhoeff staining that additionally showed absence of elastic fibers in the papillary dermis.

Case report

A 77-year-old woman, who was otherwise healthy, presented with multiple white-yellowish millimetric, monomorphic, non-follicular papules, on the posterior cervical region (Figs. 1 and 2). These lesions had been present for several years, and except for mild pruritus, were asymptomatic.

Physical examination, including peripheral pulses and cardiovascular evaluation, revealed normal findings. Cutaneous biopsy revealed an ill-defined nodular area in the superficial and mid-reticular dermis, characterized by slight thickening of the collagen fibers and by focally enlarged elastic fibers (Fig. 3). These findings were highlighted in the Verhoeff-Van Gieson staining, which further showed absence of elastic fibers in the papillary dermis (Fig. 4). Calcification of elastic tissue was not seen.

Discussion

Clinicopathological correlation favored the hypothesis of white fibrous papulosis of the neck (WFPN). In this context, the authors decided on a watch-and-wait approach; the lesions currently remain stable.

WFPN was first described by Shimizu et al. in 1985. A few years later, the same authors reported this condition in a group of 32 Japanese patients.¹ Although initially reported mainly in Japanese men, it also affects Caucasian women, from the 5th to the 9th decades of life.² WFPN is a rare acquired fibroelastolytic disorder, which presents clinically as yellowish-white round or oval papules that occur more frequently on the posterior neck region, but also on the back, without associated systemic manifestations. Its etiopathogenesis, not fully understood, seems to be related to intrinsic skin photoaging, but is probably multifactorial.^{3,4}

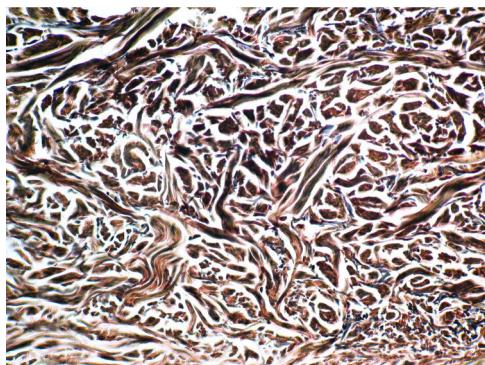

Figure 4 Thickening of collagen bundles and multifocal coarse thickening of the elastic fibers (Verhoeff, $\times 200$).

The clinical relevance of this entity lies in its broad differential diagnosis, especially with pseudoxanthoma elasticum (PXE), a genetic disease caused by a mutation in the ABCC6 (ATP-binding cassette sub-family C member 6) gene and is associated with ectopic mineralization of the skin, eyes, and blood vessels.^{5,6} However, in contrast to the latter, WFPN usually appears late in life, is not associated with systemic complications, and does not require further investigation.³ Histological examination reveals dermal fibrosis consisting of circumscribed areas of thickened collagen bundles in the papillary and mid-reticular dermis, as well as a variable loss of dermal elastic tissue.^{3,6} Despite its benign nature, WFPN may be cosmetically undesirable and sometimes itchy. Until now, no effective treatments have been established.² Some topical agents like tretinoin and antioxidants were tried, but improvement was not notable.^{2,7} Surgical excision may be an alternative choice of treatment in cases with circumscribed lesions.² Moreover, since WFPN is arguably a feature of photoaging or intrinsic aging, fractional non-ablative laser has been recently tried with good results.² However, none of the treatments present sufficient evidence in the literature.
