

## Cardiovascular risk analysis in atopic dermatitis patients<sup>☆</sup>

Dear Editor,

Atopic Dermatitis (AD), also known as atopic eczema, is a chronic, continuous or recurrent, pruritic inflammatory dermatosis with acute, subacute, or chronic eczematous lesions in typical locations that may vary according to age, but with a predilection for flexor regions and commonly associated with xerosis cutis.<sup>1</sup> Its etiology is multifactorial and involves genetic and environmental factors, abnormal skin barrier, among others. It is more prevalent in children (10%–20%) but may persist into adulthood (1%–7%) and affects men and women equally.<sup>2</sup> Treatment may vary according to the stage of the disease, age group, and severity, ranging from the use of moisturizers, topical corticosteroids, and calcineurin inhibitors for mild and moderate cases, to the use of systemic drugs such as cyclosporine, methotrexate, azathioprine, immunobiological (dupilumab) and, more recently, Janus Kinase inhibitors (baricitinib and upadacitinib) in severe cases.<sup>3</sup>

Chronic inflammatory diseases, such as AD, have been inconsistently associated with Cardiovascular Disease (CVD) and Cerebrovascular Accident (CVA) or stroke in epidemiological studies.<sup>4</sup> Psoriasis and rheumatoid arthritis have been shown to have increased Cardiovascular risk (CVR) compared to the general population.<sup>5</sup>

The increasing prevalence of AD in adults makes it imperative to investigate associated comorbidities. Assessment of CVR is necessary for adequate management of AD and adoption of preventive measures, and the Framingham Risk Score (FRS) is one of the most studied instruments for individuals in primary health care,<sup>6</sup> making it of great importance in the correlation analysis of AD and CVR.

Between June 2020 and July 2021, we conducted a pilot, case-control study in the Hospital do Servidor Público Estadual de São Paulo (IAMSPE), São Paulo, Brazil, and the

Complexo Hospitalar Padre Bento (CHPB), Guarulhos, Brazil. This study was approved by the IAMSPE's Ethics Committee (report nº 4.909.476) in which 60 subjects were equally distributed into both groups, matched for gender distribution, mean age, and associated comorbidities. The distribution in relation to ethnicity occurred in accordance with the general population attending the study, to represent the prevalence reported in the literature on cardiovascular diseases in the Brazilian population. However, this prevalence may vary from other already-published studies since it is directly dependent on some study particularities, such as the country of continental-dimension countries and substantial intermarriage.<sup>7</sup>

The main objectives of this study were to evaluate CVR in adults aged 30 years and older with AD, compare them to control subjects, and correlate AD severity with CVR. Stratification of CVR, which estimates the probability of outcomes such as acute myocardial infarction and CVA in the next 10 years, was applied through the FRS calculator, which considers parameters such as gender, age, serum total and HDL cholesterol levels, hypertension, diabetes, and smoking. Participants in the case group were selected according to the diagnostic criteria for AD proposed by the United Kingdom Working Party,<sup>8</sup> and disease severity was assessed by the Scoring Atopic Dermatitis (SCORAD) index, which evaluates the extent and intensity of lesions, as well as the presence of subjective symptoms such as pruritus and sleep loss.<sup>9</sup> The prolonged use of systemic therapy for the management of AD symptoms in patients who did not obtain adequate control after topical treatment of lesions was also taken into account as a complementary criterion in the estimation of severity. Drugs considered for pooled analysis were cyclosporine, methotrexate, azathioprine, and dupilumab.

The results of the analyses showed that there was no significant difference in CVR between the groups studied ( $p=0.941$ ) and that the variables evaluated were statistically independent (Table 1). However, age showed a strong correlation with increased CVR in participants in the case group ( $p<0.001$ ), as did systolic ( $p=0.001$ ) and diastolic

**Table 1** Comparison of parameters associated with increased cardiovascular risk between groups.

		Average	Median	Standard deviation	Q1	Q3	N	IC	p-value

blood pressure ( $p=0.028$ ) (Table 2). We did not observe a direct relationship between AD severity and CVR when using SCORAD ( $p=0.388$ ) (Table 2 and Fig. 1).

When dividing the case group into severe and non-severe, adopting prolonged treatment with systemic medications as the severity criterion, and comparing them to the control group, we observed that there was no statistical difference in relation to CVR ( $p=0.485$ ) (Table 3).

Recent studies in AD patients have shown divergent results regarding an increase in CVR.<sup>10</sup> In 2022, Ribeiro published a comprehensive review that evaluated a series of studies wherein the relationship between severe AD was evaluated regarding its inflammatory mechanisms and the risk of developing CVD.<sup>10</sup> A total of 52 trials were included in that review, encompassing meta-analyses, cohorts, reviews, and cross-sectional studies. Thirty-six studies found a correlation between AD and CVD, while 16 did not. The authors concluded that there is insufficient evidence that AD alone is a risk factor for CVD and that CVR in moderate to severe AD may be a confounding variable.

Numerous risk-assessment instruments for the development of CV diseases have been created to date. We did not find any manuscript that evaluated CVR using the Framingham global risk score, which is one of the most studied CVR-stratification instruments and validated for use in the general population in primary health care. Using the Global Risk Score, we found that despite the fact that the case group had a higher average CVR than the control group, there was no statistically significant difference between them ( $p=0.941$ ). Using SCORAD to measure the

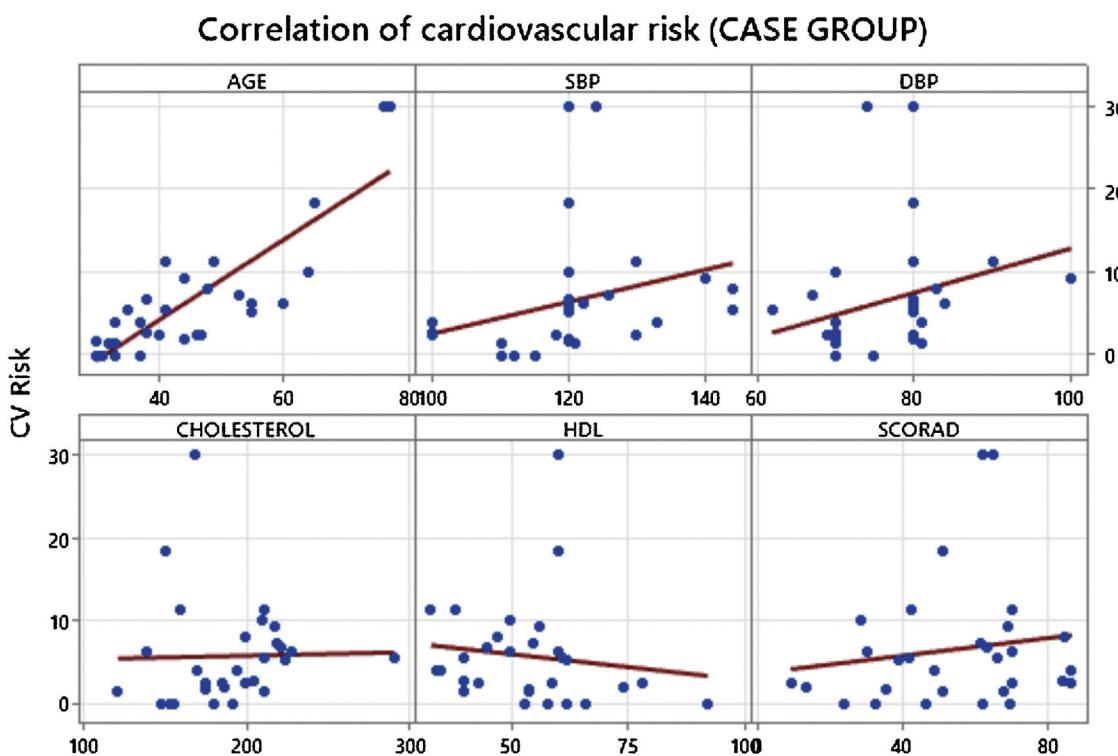

**Table 2** Correlation of cardiovascular risk with the main parameters assessed in the case group.

	CV Risk	
	Corr (r)	p-value
Age	0.800	<0.001

severity of AD, we did not observe a significant correlation with CVR ( $p=0.388$ ). When classifying the severity of AD, taking into account the use of systemic medications, and comparing individuals with severe disease, non-severe disease, and the control group, we did not observe a statistically significant difference ( $p=0.485$ ), suggesting that the severity of AD does not directly imply the increased CVR.

Given the above, our primary findings corroborate the current guidelines of the American Academy of Dermatology,<sup>11</sup> which, when evaluating a series of studies with a large number of participants with associated AD and increased CVR, did not identify evidence that demonstrated a magnitude of sufficient association to set a direct relationship up, concluding that screening for CVR in patients

**Figure 1** Correlation of cardiovascular risk with the main parameters assessed in the case group. SBP, Systolic Blood Pressure; DBP, Diastolic Blood Pressure; HDL, High Density Lipoprotein Cholesterol; SCORAD, Scoring Atopic Dermatitis.

**Table 3** Comparison of severe, non-severe, and control cases in relation to CVR.

CV Risk in %		Average	Median	Deviation standard	Q1	Q3	N	IC	p-value
Severe case	Severe case	6.57	3	8.63	1	8	23	3.53	0.485
	Non-severe case	6.33	6	3.25	5	8	7	2.41

CV risk, Cardiovascular Risk; Severe case, Patients with severe atopic dermatitis classified by prolonged use of systemic therapy; Non-severe case, Patients with atopic dermatitis who do not use systemic therapy.

with AD would not be necessary. Even though there is a correlation between the endothelial inflammatory process and the presence of biomarkers associated with the Th2 response, and some evidence that demonstrates small associations of AD and elevated CVR, or some diseases that predispose it, there are currently no indications for further cardiovascular screening and treatment of patients with AD beyond what is already recommended for the general population.

We, therefore, conclude that although blood pressure and age are strongly related to elevated CVR in individuals in the case group, they are still not considered sufficient to claim that adult individuals with AD are more likely to develop CVD than individuals in the control group. The severity of AD, as measured by the SCORAD, as well as the use of systemic therapy, did not show a direct association with increased CVR, therefore, there is no need to perform additional screening measures for CVD in this population, and AD should therefore not be considered an independent factor for CVR. Therefore, we believe that CVR assessment for AD patients should be conducted according to age-based protocols and other associated factors.

## Dermoscopic changes of tattoos over melanocytic nevi<sup>☆</sup>

Dear Editor,

The prevalence of tattoos in the population has increased and dermatologists must be familiar with its complications. The survey carried out by Kluger et al. showed a prevalence of tattooed individuals in Brazil of 22.3%; the most prevalent age group being 25–34 years old (30.3%).<sup>1</sup> Bicca et al. analyzed the prevalence of tattoos in recruits in Pelotas, Rio Grande do Sul, and the result was 10.82% of 1,968 recruits.<sup>2</sup>

Nevi traumatized by tattooing may undergo changes that increase the suspicion of malignancy, such as cytological atypia, pagetoid spreading and dermal mitosis; therefore, nevi, pigmented lesions, or melanoma scars should not be tattooed. Tattooing pigment in nevi can either delay the diagnosis of malignant transformation or simulate findings of malignancy, resulting in unnecessary surgery. It is recommended to avoid tattooing areas of the body with an abundance of nevi, keeping a margin of 0.5 to 1 cm from these lesions. Patients with atypical nevi syndrome or a personal or family history of melanoma should consult a dermatologist prior to tattooing.<sup>3–6</sup>

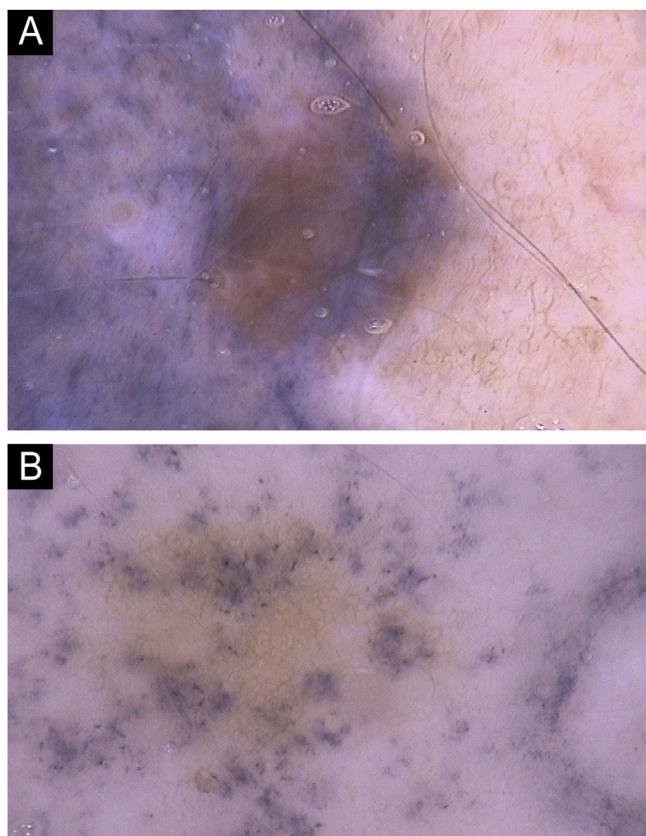

A cross-sectional study was carried out, using convenience sampling between December 2021 and July 2022, at the Dermatology Outpatient Clinic of Hospital de Clínicas de Porto Alegre, in Porto Alegre, Rio Grande do Sul, Brazil. The inclusion criterion was having a tattoo. Exclusion criteria were being under 18 years of age or having some physical or psychiatric disability that made it impossible to understand the study and/or sign the Informed Consent Form. The tattoos were inspected and when they were over a nevus, the lesion was photographed and stored using a FotoFinder equipment. The dermoscopic characteristics were analyzed jointly by the researchers. This study was approved by the Ethics Committee under protocol number 52210121.2.0000.5327.

A total of 112 individuals participated in the research, who had 485 tattoos. Of these, 82 (16.9%) were located over melanocytic nevi, with a total of 194 nevi being tattooed. The study by Kluger retrospectively analyzed complications in 31 patients with tattoos and observed 10% tattooed nevi.<sup>7</sup> This value is lower than that was found in the present study, which can be justified because this was a cross-sectional

study in which all tattoos were inspected actively looking for nevi.

The following dermoscopic changes were observed in tattooed nevi: dots, globules, erythema, tattoo obliteration, amorphous blurring, blue veil, densification of the nevus pigment, partial obliteration of the nevus pigment, total obliteration of the nevus pigment, pseudonetwork and perifollicular pigment. Figs. 1–4 demonstrate some aspects observed in the study.

Blurring was seen as amorphous dark areas in the nevus, and was the most observed change, present in 108 nevi (55.7%). Tattooing pigment present in small dots was present in 93 nevi (47.9%); while larger round clusters with the appearance of globules were present in 70 nevi (36.1%). Tattooing pigment present in small quantities in the nevus

**Fig. 1** (A) Tattoo pigment in an amorphous blurring pattern with an area of densification of the melanocytic network on the left edge and an area of blue veil on the lower edge of the nevus. (B) Tattoo pigment in a pattern of dots and globules.
